Abstract. A formal framework is proposed for the verification of complex real-time systems, modeled as client-server scheduling systems, using the popular model-checking approach. Model-checking is often restricted by the large state-space of complex real-time systems. The scheduling of tasks in such systems can be taken advantage of for model-checking. Our implementation and experiments corroborate the feasibility of such an approach. Wide-applicability, significant state-space reduction, and several scheduling semantics are some of the important features in our theory and implementation.

1 Introduction

Model-checking has the promise of a formal, full, and automatic verification of complex industrial implementations in the future. In spite of the recent success in the formal verification of real-time systems, it is still quite infeasible to formally verify large-scale real-world systems due to their high degree of complexity. On the other hand, engineers have developed various paradigms to help build and verify safer systems. One such paradigm is the scheduling paradigm which greatly simplifies the interaction among many processes to periodical and aperiodical computation time contention. But still, scheduling paradigm represents a too much simplified paradigm for many complex systems, such as protocol design, client-server systems, communication systems, In this paper, we construct a theoretical framework which combines the advantages of model-checking and scheduling paradigm with several concurrent scheduling servers employing different scheduling policies. Our implementation and experiments show its benefit and feasibility by comparing with a naive verification effort, that is, pure model-checking approach. Experiment data shows that exponential reduction in state-space size can be reached.

In our framework, a *scheduling client-server system* consists of a set of *servers*, with scheduling policies specified, and a set of *scheduling client automata* which are basically real-time automata extended with scheduling tasks specified at different modes. One major issue in such systems is the difficulty of compromising between two time scales : the *job-computation time unit* Δ_J and the *schedulability-check time unit* Δ_S . Usually Δ_J is several orders of magnitude larger than Δ_S . In real-time systems model-checking, very often the time and space complexities are proportional to the timing constants used in the system description. With such a big disparity between Δ_J and Δ_S , the complexity of scheduling system model-checking can easily grow beyond manageable. In this work, we adopted the following technique. The systems will still be presented with time unit Δ_J . But, when we are in a mode to check the schedulability, we shall

derive formulas, with respect to different scheduling policies, to calculate the computation time γ_S for the schedulability-check. Then the duration of the schedulability-check is set to be $\lceil \frac{\gamma_S}{\Delta_J} \rceil$ in the time unit of Δ_J . With this technique, we can circumvent the potential combinatorial complexities caused by the disparity between the two time-scales.

Another major issue is: when exactly should the checking for schedulability of the tasks in a mode be performed. Two alternatives arise here, namely, (1) checking before an in-coming transition of the mode is taken, or (2) checking after an in-coming transition of the mode is taken. Several different kinds of semantics related to schedulability checking are possible. These are discussed in subsection 3.1. Following is an example of a video system.

Example 1. : Video System

Here, we have two servers and two clients in a *Video-on-Demand* system illustrated in Fig. 1. The two clients issue task service requests to both the servers concurrently. The two servers check if requests are schedulable and then either acknowledge or reject the requests. The server for movies schedules with the *rate-monotonic* (RM) scheduling policy while the other does with the *earliest deadline first* (EDF) scheduling policy. The explanation of some popular scheduling policies can be found in section 2.

The *Movie Server* stores a set of movie files ready for access by clients under the rate-monotonic scheduling policy. The *Commercials Server* stores a set of commercial files and work with the earliest-deadline first scheduling policy. As shown in Fig. 1, the clients are modeled by finite-state automata that are enhanced with clocks and scheduling tasks. In the figure, boxes represent different operational modes of the clients and the arrows represent transitions between modes. x and y are the two clocks used to control the operation times in the client automata. For example, the assignment $x := 0$ beside an arrow means that the clock x is reset to zero during the transition. The predicate $x = 35$ on an out-going transition in Client A means that the transmission of movie “Pretty Woman,” should end at 35 time units.

Within each box, we specify tasks by a tuple (α, c, p, d, f) where α is the server identification, c is the computation time of the task within each period, p is the period for the task, d is the deadline for each instance of a task, and f specifies if fixed priority ($f = 1$) or dynamic priority ($f = 0$) is to be used. It is important that at any instant of the computation, the tasks set admitted to each server remains schedulable. \parallel

The outline of this paper is as follows. Section 2 gives a brief survey of the priority scheduling policies used in our system. Section 3 presents the formal system model and describes how model-checking is used to verify the system. Section 4 describes our implementation of the model-checking approach using the popular HyTech tool and shows the benefit of our approach using some application examples. Section 5 concludes the paper.

In the following, we use \mathcal{N} and \mathcal{R}^+ to denote the set of non-negative integers and the set of non-negative real numbers.

2 Review of scheduling research

A real-time system generally needs to process various concurrent tasks. A *task* is a finite sequence of computation steps that collectively perform some required action

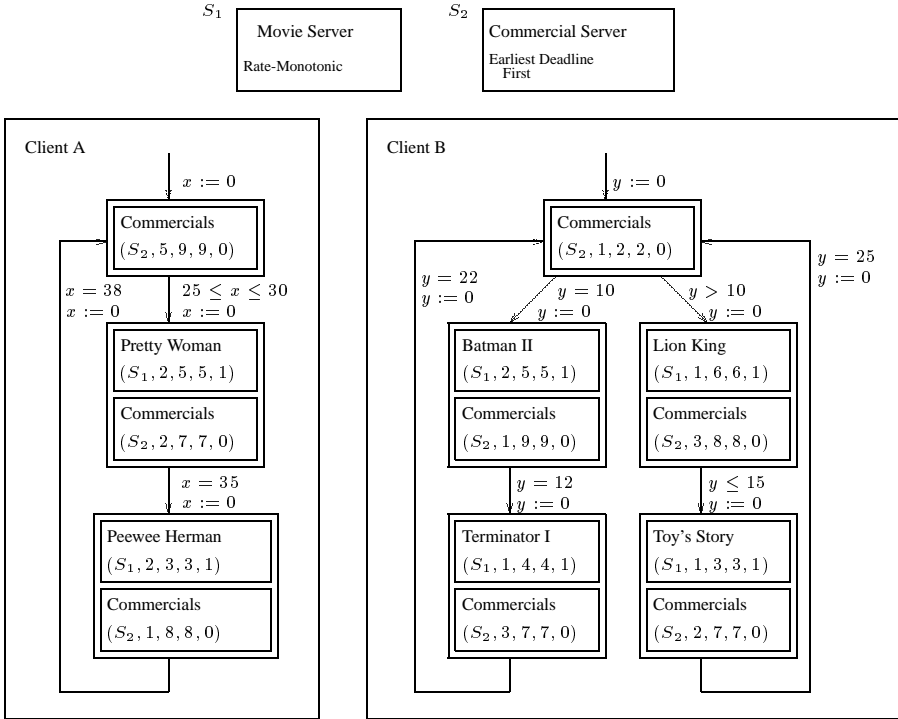

Fig. 1. A video-on-demand system

of a real-time system and may be characterized by its execution time, deadline, etc. *Periodic* tasks are tasks that are repeatedly executed once per period of time. Each execution instance of a periodic task is called a *job* of that task. In a processor-controlled system, when a processor is shared between time-critical tasks and non-time-critical ones, efficient use of the processor can only be achieved by careful scheduling of the tasks. Here, time-critical tasks are assumed to be preemptive, independent, periodic, and having constant execution times with hard, critical deadlines. Scheduling may be *time-driven* or *priority-driven*. A time-driven scheduling algorithm determines the exact execution time of all tasks. A priority-driven scheduling algorithm assigns priorities to tasks that determines which task is to be executed at a particular moment. We mainly consider time-critical periodic tasks with the above assumptions and scheduled using priority-driven scheduling algorithms.

Depending on the type of priority assignments, there are three classes of scheduling algorithms: *fixed priority*, *dynamic priority*, and *mixed priority* scheduling algorithms. When the priorities assigned to tasks are fixed and do not change between job executions, the algorithm is called fixed priority scheduling algorithm. When priorities

change dynamically between job executions, it is called dynamic priority scheduling. When a subset of tasks is scheduled using fixed priority assignment and the rest using dynamic priority assignment, it is called mixed priority scheduling.

Before going into the details of scheduling algorithms, we define the task set to be scheduled as a set of n tasks $\{\phi_1, \phi_2, \dots, \phi_n\}$ with computation times c_1, c_2, \dots, c_n , request periods p_1, p_2, \dots, p_n , and phasings h_1, h_2, \dots, h_n . A task ϕ_i is to be periodically executed for c_i time units once every p_i time units. The first job of task ϕ_i starts execution at a time h_i . The worst-case phasing called a *critical instant* occurs when all $h_i = 0$, for all i , $1 \leq i \leq n$.

Liu and Layland [LL73] proposed an optimal fixed priority scheduling algorithm called the *rate-monotonic* (RM) scheduling algorithm and an optimal dynamic priority scheduling algorithm called *earliest-deadline first* (EDF) scheduling. The RM scheduling algorithm assigns higher priorities to tasks with higher request rates, that is, smaller request periods. Liu and Layland proved that the worst case utilization bound of RM was $n(2^{1/n} - 1)$ for a set of n tasks. This bound decreases monotonically from 0.83 when $n = 2$ to $\log_e 2 = 0.693$ as $n \rightarrow \infty$. This result shows that any periodic task set of any size will be able to meet all deadlines all of the time if RM scheduling algorithm is used and the total utilization is not greater than 0.693.

The exact characterization for RM was given by Lehoczky, Sha, and Ding [LSD89], they proved that given periodic tasks $\phi_1, \phi_2, \dots, \phi_n$ with request periods $p_1 \leq p_2 \leq \dots \leq p_n$ computation requirements c_1, c_2, \dots, c_n , and phasings h_1, h_2, \dots, h_n , ϕ_i is schedulable using RM iff

$$\text{Min}_{\{t \in G_i\}} W_i(t)/t \leq 1 \quad (1)$$

where $W_i(t) = \sum_{j=1}^i c_j \lceil t/p_j \rceil$, the cumulative demands on the processor by tasks over $[0, t]$, 0 is a critical instant (i.e., $h_i = 0$ for all i), and $G_i = \{k \cdot p_j \mid j = 1, \dots, i, k = 1, \dots, \lfloor p_i/p_j \rfloor\}$.

Liu and Layland discussed the case when task deadlines coincide with request periods, whereas Lehoczky [L90] considered the fixed priority scheduling of periodic tasks with *arbitrary* deadlines and gave a feasibility characterization of RM in this case: given a task set with arbitrary deadlines $d_1 \leq d_2 \leq \dots \leq d_n$, ϕ_i is RM schedulable iff $\text{Max}_{k \leq N_i} W_i(k, (k-1)p_i + d_i) \leq 1$ where $W_i(k, x) = \min_{t \leq x} ((\sum_{j=1}^{i-1} c_j \lceil t/p_j \rceil + kc_i)/t)$ and $N_i = \min\{k \mid W_i(k, kp_i) \leq 1\}$.

The worst case utilization bound of RM with arbitrary deadlines was also derived in [L90]. This bound (U_∞) depends on the common deadline postponement factor Δ , i.e., $d_i = \Delta p_i$, $1 \leq i \leq n$.

$$U_\infty(\Delta) = \Delta \log_e \left(\frac{\Delta + 1}{\Delta} \right), \Delta = 1, 2, \dots \quad (2)$$

For $\Delta = 2$, the worst case utilization increases from 0.693 to 0.811 and for $\Delta = 3$ it is 0.863.

Recently, the timing analysis for a more general hard real-time periodic task set on a uniprocessor using fixed-priority methods was proposed by Härbour et al [HKL94].

Considering the earliest deadline first dynamic priority scheduling, Liu and Layland [LL73] proved that given a task set, it is EDF schedulable iff

$$\sum_{i=1}^n \frac{c_i}{p_i} \leq 1 \quad (3)$$

and showed that the processor utilization can be as high as 100%.

Liu and Layland also discussed the case of *Mixed Priority* (MP) scheduling, where given a task set $\phi_1, \phi_2, \dots, \phi_n$, the first k tasks ϕ_1, \dots, ϕ_k , $k < n$, are scheduled using fixed priority assignments and the rest $n - k$ tasks $\phi_{k+1}, \dots, \phi_n$ are scheduled using dynamic priority assignments. It was shown that considering the accumulated processor time from 0 to t available to the task set ($a_k(t)$), the task set is mixed priority schedulable iff

$$\sum_{i=1}^{n-k} \left\lfloor \frac{t}{p_{k+i}} \right\rfloor c_{k+i} \leq a_k(t) \quad (4)$$

for all t which are multiples of p_{k+1} or \dots or p_n . Here, $a_k(t)$ can be computed as follows.

$$a_k(t) = t - \sum_{j=1}^k c_j \left\lceil \frac{t}{p_j} \right\rceil$$

Although the EDF dynamic priority scheduling has a high processor utilization, in recent years fixed priority scheduling has received great interests from both academy and industry [LSD89, L90, SG90, HKL91, SKG91, TBW92, KAS93, HKL94].

Summarizing the above scheduling algorithms, we have five different cases of schedulability considerations:

- RM-safe: all task sets are schedulable as long as the server utilization is below $\log_e 2 = 0.693$,
- RM-exact: all task sets satisfying Equation (1) are schedulable,
- RM-arbitrary: all task sets are schedulable as long as the server utilization is below $\Delta \log_e((\Delta + 1)/\Delta)$ (Equation (2)),
- EDF: all task sets satisfying Equation (3) are schedulable,
- MP: all task sets satisfying Equation (4) are schedulable,

3 Client-Server Scheduling System Model

Modeling a real-time system as a client-server scheduling system, our target system of verification consists of a constant number m of *servers* that perform scheduling and a constant number n of *clients* that issue scheduling requests. A server adopts a scheduling policy. Each client is modeled with a client automaton such that the client issues different scheduling requests in various modes. On receiving a request for scheduling a set of tasks, a server decides whether the tasks are currently schedulable or not.

Definition 1. : A Periodic Task

A periodic task is a tuple $\phi = (\alpha, c, p, d, f)$, where α is the identification of the server on which the task is to be processed, c is the constant computation time of a job, p is the

request period of a job, d is the deadline within which a job must be completed before the next job request occurs, and f specifies if the task must be scheduled using fixed priority or dynamic priority, that is, $f = 1$ for fixed priority and $f = 0$ for dynamic priority, $c \leq p$, $c \leq d$, and $c, p, d \in \mathcal{N}$, the set of nonnegative integers. \parallel

Notationally, we let $T_{\mathcal{H}}$ be the universal set containing all possible tasks in a system \mathcal{H} . We model the behavior of clients with timed automata which are automata enhanced with clocks. It is assumed that the current mode of each client is broadcast to all the clients in the same system. The behavior of a client in each mode can be expressed through a *state predicate*, which is a combination of propositions and timing inequalities on clock readings. Given a set of propositions P and a set of clocks X , a state predicate η of P and X has the following syntax.

$$\eta ::= \text{false} \mid r \mid x \sim a \mid x + a_1 \sim y + a_2 \mid \eta_1 \wedge \eta_2$$

where $r \in P$, $x, y \in X$, a, a_1 , and a_2 are rational numbers, $\sim \in \{\leq, <, =, \geq, >\}$, and η_1, η_2 are state predicates. Let $B(P, X)$ be the set of all state predicates on P and X . Given a set of propositions P and a set of clocks X , a client is modeled as follows.

Definition 2. : Client Automaton (CA)

A *Client Automaton* (CA) is a tuple $C = (M, m^0, P, X, \chi, \mu, E, \rho, \tau)$ with the following restrictions.

- M is a finite set of modes.
- $m^0 \in M$ is the initial mode.
- P is a set of atomic propositions.
- X is a set of clocks.
- $\chi : M \mapsto B(P, X)$ is a function that labels each mode with a condition true in that mode.
- $\mu : M \mapsto 2^{T_{\mathcal{H}}}$ maps each mode to a finite subset of tasks in $T_{\mathcal{H}}$.
- $E \subseteq M \times M$ is the set of transitions.
- $\rho : E \mapsto 2^X$ maps a transition to a set of clocks that are reset on that transition.
- $\tau : E \mapsto B(P, X)$ maps each transition to a triggering condition. \parallel

The CA C starts execution at its mode m^0 . We shall assume that initially, all clocks read zero. In between transitions, all clocks increment at a uniform rate. The transitions of the CA may be fired when the triggering condition is satisfied.

Definition 3. : Servers

A server is a tuple $\langle \alpha, \phi \rangle$ where α is the unique identification for the server and ϕ is the scheduling policy of the server. \parallel

Now with a set of servers, a set of client automata, and the ratio between the schedulability-check time unit and the job-computation time unit, we are ready to define what is a *scheduling system*.

Definition 4. : Scheduling systems

A *scheduling system* \mathcal{H} is defined as a tuple $(\{S_1, S_2, \dots, S_m\}, \{C_1, C_2, \dots, C_n\}, P, X, \Gamma)$, where $\{S_1, S_2, \dots, S_m\}$ is a set of servers, $\{C_1, C_2, \dots, C_n\}$ is a set of client automata, P , and X are respectively the set of atomic propositions and the set of clocks used in C_1, \dots, C_n , and Γ is a ratio of a schedulability-check time unit to a job computation time unit. \parallel

Definition 5. : States and their admissibility

Given a system $\mathcal{H} = (\{S_1, \dots, S_m\}, \{C_1, \dots, C_n\}, P, X, \Gamma)$ with $C_i = (M_i, m_i^0, P, X, \chi_i, \mu_i, E_i, \rho_i, \tau_i)$, a state s of \mathcal{H} is defined as a mapping from $\{1, \dots, n\} \cup P \cup X$ to $\bigcup_{1 \leq i \leq n} M_i \cup \{true, false\} \cup R^+$ such that

- $\forall i \in \{1, \dots, n\}, s(i) \in M_i$ is the mode of C_i in s ;
- $\forall r \in P, s(r) \in \{true, false\}$ is the truth value of r in s ; and
- $\forall x \in X, s(x) \in R^+$ is the reading of clock x in s .

Further, a state s is said to be *admissible* when:

- $s \models \bigwedge_{1 \leq i \leq n} \chi_i(s(i))$, and
- the task set $\bigcup_{1 \leq i \leq m} \mu_i(s(i)) \subseteq T_{\mathcal{H}}$ at s is schedulable by the servers. ||

Definition 6. : Satisfaction of state predicate by a state

State predicate η is satisfied by a state s , written as $s \models \eta$ iff

- $s \not\models false$;
- $\forall r \in P, s \models r$ iff $s(r) = true$;
- $\forall x \in X, s \models x \sim a$ iff $s(x) \sim a$;
- $\forall x, y \in X, s \models x + a_1 \sim y + a_2$ iff $s(x) + a_1 \sim s(y) + a_2$; and
- $s \models \eta_1 \wedge \eta_2$ iff $s \models \eta_1$ and $s \models \eta_2$ ||

Definition 7. : Mode Transition

Given a system $\mathcal{H} = (\{S_1, \dots, S_m\}, \{C_1, \dots, C_n\}, P, X, \Gamma)$ with $C_i = (M_i, m_i^0, P, X, \chi_i, \mu_i, E_i, \rho_i, \tau_i)$, and two states s and s' , there is a *mode transition* from s to s' in \mathcal{H} , in symbols $s \rightarrow s'$, iff

- both s and s' are admissible states,
- there is an $1 \leq i \leq n$ such that
 - $(s(i), s'(i)) \in E_i$;
 - $s(i) \models \tau_i(s(i), s'(i))$;
 - for all $1 \leq j \leq n$ and $j \neq i, s(j) = s'(j)$;
 - $\forall x \in X ((x \in \rho_i(s(i), s'(i)) \Rightarrow s'(x) = 0) \wedge (x \notin \rho_i(s(i), s'(i)) \Rightarrow s'(x) = s(x)))$. ||

Given a state s and a $\delta \in \mathcal{R}^+$, we let $s + \delta$ be the state that agrees with s in every aspect except for all $x \in X, s(x) + \delta = (s + \delta)(x)$.

3.1 Semantics of Schedulability Checking

The admissibility of a new state, that is, the schedulability check, can be implemented in either one of two ways: (1) checking before transition, and (2) checking after transition. In the former case, when a client is in a particular mode (may be executing some tasks) and an out-going transition is enabled, it must first check with the servers by sending scheduling requests before the out-going transition is taken. In the latter case, when a client is in a particular mode and an out-going transition is enabled, the client may take the transition and then check if the tasks in the new mode are schedulable.

(a) *Scheduling-Check Before Transition* (SCBT): The semantics here differ mainly in the duration time that a client automata can stay in a mode. Here, we propose three possibilities.

- **(SPR) Saturated Parallel Request:** If more than one out-going transitions of the currently executing mode are concurrently enabled, then the client keeps on issuing scheduling requests to all servers according to its next-states task sets. Once a positive response is back for any one next-state, the client can make the corresponding transition. If more than one positive responses are received, the client makes all corresponding transitions in parallel (parallelism is implemented as interleaving of transition sequences). In this semantics, the duration time of a mode must be greater than the schedulability-check computation time for the corresponding next state. This semantics needs minimal modification to translate to HyTech input form.
- **(SQR) Sequential Request:** The client nondeterministically chooses a next state and posts requests to the servers specified in the task set of the next state. No request to any server will be issued until the last request is replied. In this semantics, the client nondeterministically chooses a next-state and polls the servers for schedulability-check. Only after response is back, the client may test for another next-state. Thus the duration time a client can stay in a mode must be the sum of a sequence of schedulability-check computation times.
- **(NPR) Non-saturated Parallel Request:** The client polls all the servers for all its next-states. Once a reply is back, the client choose between taking the corresponding transition or not. If it does not transit at the moment, then it issues another schedulability request for the same next-state. In this semantics, the duration time must be at least a multiple of the schedulability-check computation time for a particular next-state.

(b) *Scheduling Check After Transition (SCAT):* In this case, modularity of the system specifications is preserved and transitions occur according to the timed automata semantics. Scheduling systems implemented using this scheme of schedulability checking have two semantics related to scheduling, that is *strict scheduling semantics* and *loose scheduling semantics*.

- **(SSS) Strict Scheduling Semantics:** In a particular mode, it may happen that the specified task set cannot be scheduled before an out-going transition is enabled. In this situation, when we do not allow the client to make the enabled transition from the non-scheduled mode, we call it strict scheduling semantics.
- **(LSS) Loose Scheduling Semantics:** In a specific mode, when the specified tasks are not scheduled (i.e., schedulability-check returns negative response) before an out-going transition is enabled, the client may choose to either keep on issuing scheduling requests for non-scheduled tasks set or transit to the next mode by making the enabled transition. This is called *loose scheduling semantics* and results in a larger global state space as shown by examples in Section 4.

The computation of our scheduling system is defined in the following.

Definition 8. : *s*-run

Given a system \mathcal{H} and a state s of \mathcal{H} , a computation of \mathcal{H} starting at s , called an *s*-run, is a sequence $((s_1, t_1), (s_2, t_2), \dots)$ of pairs such that

- $s = s_1$; and
- for each $t \in \mathcal{R}^+$, $\exists j \in \mathcal{N}$ such that $t_j \geq t$; and

- for each integer $j \geq 1$, for each real $0 \leq \delta \leq t_{j+1} - t_j$, s_j is admissible and $s_j + \delta \models \chi_i(s_j(i))$; and
- for each $j \geq 1$, \mathcal{H} goes from s_j to s_{j+1} because of
 - mode transition, i.e. $t_j = t_{j+1} \wedge s_j \rightarrow s_{j+1}$; or
 - time passage, i.e. $t_j < t_{j+1} \wedge s_j + t_{j+1} - t_j = s_{j+1}$.
- The duration time a client can stay in a mode must satisfy the chosen semantics. ||

4 Implementation

The theoretical framework of a Client Server Scheduling System Model as presented in Section 3 has been implemented into a practical tool for verifying scheduling systems. The implementation mainly constitutes two parts: scheduling check time computation and translating a scheduling system description into a pure timed automata specification. The resulting timed automata specification can be seen as a special case of linear hybrid automata, hence the popular tool called HyTech is used for verifying our resultant system descriptions.

The two semantics of scheduling check before and after transition have both been implemented into our translator tool. Experiments have been conducted with several application examples from both hardware and software. Though the degree of advantage in using our proposed approach for verifying scheduling systems vary, yet all of the examples show an appreciable amount of decrease in the size of the reachable state space required for verification.

4.1 Scheduling Check Time Computation

Before entering a state s , a system must check with the servers if it is an admissible state, that is, if all the tasks ($\cup_{i=1}^n \mu_i(s(i))$) in that state are schedulable by the servers. This computation for schedulability check is done exclusively by each client by locking the servers and requires a small period of time which depends on the scheduling algorithms used by the servers. Usually the computation for schedulability check is a very small one compared to the scheduled job computation time. However, as the number of contending processes increases, some scheduling policies may consume an amount of time that cannot be considered negligible. For example, for a 200 MHz CPU, the processor cycle time is around 5×10^{-8} seconds, and considering a single instruction to be 2 cycles, the CPU requires only 10^{-7} seconds for one processor operation. At the same time, one tick of scheduled job computation time in a real-time system is usually in the order of a millisecond (ms). Hence, the ratio of a server cycle time to a job computation time unit is 10^{-4} . Normally, a task set size in a real-time system is in the order of 10 to 100. A schedulability-check time linear in the size of the task set would be negligible compared to the computation time of the task set, but if it is quadratic, it would be in the order of one job time unit.

For analyzing the amount of time required for schedulability-check, we define the set of tasks in some state s , which are to be scheduled on some particular server S_k using some scheduling algorithm R_k , $1 \leq k \leq m$.

$$\nu_s(R_k) = \{\phi \mid \phi = (S_k, c, p, d, f), \phi \in \mu_i(s(i)), 1 \leq i \leq n\} \quad (5)$$

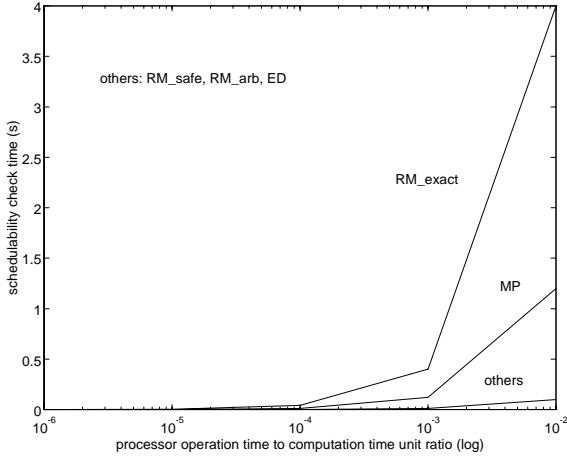

Fig. 2. Schedulability Check Time

The schedulability check time required for each of the five variations of priority scheduling described in section 2 using different ratios of server operation time to computation time unit is illustrated in Fig. 2. We observe that the schedulability check time is negligible when the ratio is of the order of (10^{-4}). We make the following assumptions:

- The execution of all jobs of each task start at integer-valued time instants.
- A schedulability check is assumed to take 1 computation time unit when it is not greater than 1 unit and it is taken as 2 time units when it is between 1 and 2, that is, the schedulability check time is taken as the next larger integer if it is not already an integer.

As far as RM-safe, RM-arbitrary, and EDF priority scheduling are concerned, the schedulability check time only depends on the total utilization of a server. As long as the utilization is below the respective bounds of $n(2^{1/n} - 1)$, $\Delta \log_e \left(\frac{\Delta+1}{\Delta} \right)$, and 100%, all tasks of all phasings, request periods, and deadlines can be scheduled. This check requires time linear in $|\nu_s(R)|$, where R is RM-safe, RM-arbitrary, and EDF, respectively. Hence, assuming the ratio of a processor operation time to a job computation time unit to be t_{op} , for example, t_{op} is in the order of 10^{-4} for a 200 MHz CPU and a 1 ms tick computation time, the time spent for checking schedulability of RM-safe, RM-arbitrary, and EDF by a particular server are as follows.

$$\gamma_s(RM_{safe}) = |\nu_s(RM_{safe})| \times t_{op} \quad (6)$$

$$\gamma_s(RM_{arb}) = |\nu_s(RM_{arb})| \times t_{op} \quad (7)$$

$$\gamma_s(EDF) = |\nu_s(EDF)| \times t_{op} \quad (8)$$

For RM-exact (Equation 1) scheduling, the schedulability check time is as follows.

$$\gamma_s(RM_{exact}) = |\nu_s(RM_{exact})|^2 \times p_{|\nu_s(RM_{exact})|} \times t_{op} \quad (9)$$

where $p_{|\nu_s(RM_{exact})|}$ is the largest period in $\nu_s(RM_{exact})$. As for mixed priority scheduling, the schedulability check time is as follows.

$$\gamma_s(MP) = |\nu_s(MP)| \times \text{LCM}\{p_k \mid \phi = (S, c, p_k, d, 1)\} \times t_{op} \quad (10)$$

where LCM is the least common multiple and $\phi(S, c, p_k, d, 1)$ is a task in state s , which is to be scheduled using dynamic priority.

Hence, the total time spent on schedulability check during a state transition to a state s in a system $\mathcal{H} = (\langle S_1, S_2, \dots, S_m \rangle, \langle R_1, R_2, \dots, R_m \rangle, \langle C_1, C_2, \dots, C_n \rangle, P, X, T_{\mathcal{H}}, t_{op})$ is as follows.

$$\gamma_s = \text{Max}_{1 \leq k \leq m} \gamma_s(R_k) \quad (11)$$

where $R_k \in \{RM_{safe}, RM_{exact}, RM_{arb}, EDF, MP\}$.

The difficulty in implementing scheduling check time computation lies in the fact that for RM_{exact} and MP scheduling policies, the periods of all the currently executing tasks must be known (refer to Equations (10) and (11)), hence we must consider all possible permutations of the client modes for a complete check time computation. This also implies that the mode status of each client must be broadcast to all the other clients in the scheduling system. This broadcast has been implemented in our translator.

4.2 Translator

We developed a translator for translating the client-server scheduling system specification (in our own input language) to the HyTech specification. Although a scheduling system can be specified using the HyTech input language, yet the specification would be very lengthy, tedious, and error-prone. Using our input language, the specification is short and compact and the translation is done systematically, thus avoiding any human-errors. For example, in the *real-time operating system* example (described in subsection 4.3), using our input language the specification consisted of only 12 modes and 17 transitions, whereas the resulting translation into HyTech input language consisted of 58 modes and 416 transitions. Thus, the translator is a necessity for verifying scheduling systems.

HyTech [HHWT95] is a popular verification tool for verifying systems modeled as linear hybrid automata. HyTech has been used to verify various different systems such as gas burner, railroad crossing controller, Corbett's distributed controller, and protocols such as Fischer's mutual exclusion protocol. Each client automaton is implemented as a linear hybrid automaton in HyTech and the analysis tool is used to verify our system.

According to the different scheduling semantics, we have different types of implementation schemes. For the scheduling check before transition (SCBT) semantics, we have a transition-oriented implementation and for the scheduling check after transition (SCAT), we have a mode-oriented implementation.

SCBT Implementation As illustrated in Fig. 3, each mode in the scheduling system description is implemented as a simple job execution location called *RunJobs*, but each mode transition is implemented as a set of three interconnected locations called *Lock*,

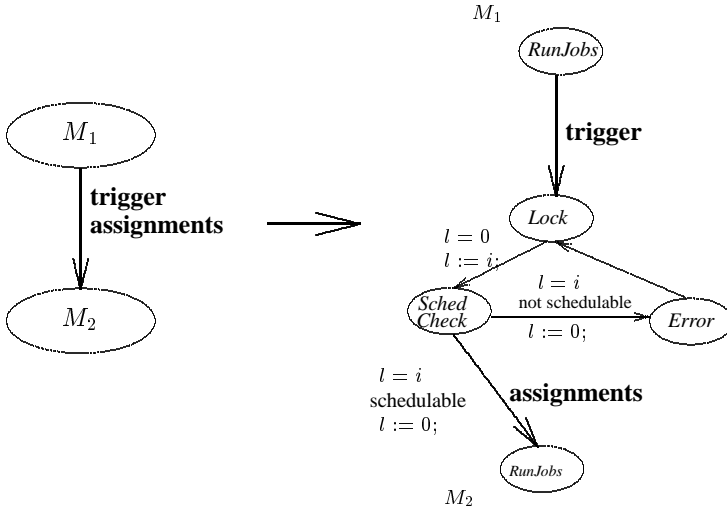

Fig. 3. Scheduling-Check Before Transition Implementation

SchedCheck, and *Error*. The purpose of these locations are, respectively, the locking of the servers, the checking for schedulability of the tasks in the next mode (the destination mode of the transition under consideration), and the resetting of internal variables when a negative response is received in *SchedCheck*. There is a location transition from *RunJob* to *Lock* and one from *SchedCheck* (on a positive response from the servers) to the *RunJobs* location of the destination mode. The triggering condition and the assignment statements of the transition under consideration are attached to the location transition from *RunJobs* to *Lock* and to the location transition from *SchedCheck* to next mode *RunJobs* location, respectively. The locking mechanism is similar to that for SCAT and is described in the SCAT implementation. Saturated parallel request (SPR) of SCBT requires the least modification with respect to HyTech, so only SPR was implemented.

SCAT Implementation Each mode of a client automaton is implemented by four locations, namely, *Lock*, *SchedCheck*, *RunJobs*, and *Error*. A client must check the admissibility of a mode before entering it, and this check must be done exclusively by a client because otherwise the schedulability check performed will not be consistent. To ensure exclusiveness of schedulability check, we employ a simpler version of the Fischer’s mutual exclusion protocol [L87] and a *lock* (l) semaphore variable. Before performing schedulability-check, a client obtains ownership of l by setting l to its identification number so that it can exclusively do the checking. A client waits in location *Lock* for l to be free (i.e., $l = 0$) and when free, it sets l to its identification number. Schedulability check is done in the location *SchedCheck* if l is still set to its own identification number, otherwise the client returns to the location *Lock*. After schedulability check, the client

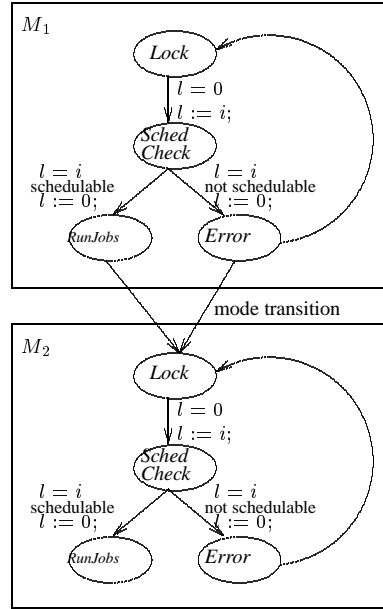

Fig. 5. SCAT: LSS Implementation

changes mode in location *SchedCheck* and if schedulable the jobs of the scheduled tasks are executed in location *RunJobs*, otherwise the location *Error* is entered.

As illustrated in Fig. 4, in the case of strict scheduling semantics (SSS), the location *Error* has only one out-going transition to location *Lock* since the tasks must be scheduled and executed in the mode before any mode transition occurs. The location transition from *RunJobs* to *Lock* implements a mode transition in the client automaton. As illustrated in Fig. 5, in the case of loose scheduling semantics (LSS), the location *Error* has two out-going transitions: one to the location *Lock* of the current mode (just as in the case of strict scheduling semantics) and one to the location *Lock* of the next mode. The two location transitions from location *Error* to the two *Lock* locations implement a mode transition.

4.3 Application Examples

To illustrate the generality of our approach, we demonstrate the benefits of three different types of systems: a hardware system such as a video-on-demand (VOD) system, a software system such as a real-time operating system (RTOS), and an agent system such as a package delivery system (PDS).

There are two servers in the video examples (just as in Fig. 1). The movie server schedules tasks with the rate-monotonic (safe) policy, while the commercial server does so with the earliest-deadline first policy. For the real-time OS example, there are four servers: OS kernel, display, memory, and printer, which use rate-monotonic (safe),

Table 1. Comparison of Pure Model Checking and Our Approach

Example	Specifications				Number of regions (convex predicates)								
	S	C	$\cup M_i$	$\cup E_i$	SCBT			SCAT					
					SPR			SSS			LSS		
					P_{MC}	S_{MC}	%	P_{MC}	S_{MC}	%	P_{MC}	S_{MC}	%
VOD(Fig. 1)	2	2	8	9	139	90	64.7	110	68	61.8	120	78	65.0
VOD1	2	3	6	7	344	231	67.2	141	92	65.2	147	98	66.7
VOD2	2	3	9	11	114	46	40.3	80	34	42.5	107	61	57.0
RTOS1	4	3	11	14	2962	2247	75.9	1980	1486	75.0	2054	1560	75.9
RTOS2	4	3	12	16	830	306	36.9	684	256	37.4	728	300	41.2
PDS1	3	4	6	6	4717	3708	78.6	2114	1610	76.1	2140	1636	76.5
PDS2	3	4	6	6	3306	1554	47.0	1193	536	44.9	1204	547	45.4

S: set of servers, C: set of clients, $|\cup M_i|$: total #modes, $|\cup E_i|$: total #transitions
 P_{MC} : Pure Model Checking, S_{MC} : Scheduling System Model Checking, %: S_{MC} / P_{MC}

earliest-deadline first, rate-monotonic (arb), rate-monotonic (exact) policies, respectively, for scheduling the tasks. For the delivery system example, it is assumed that there are three delivery agents and four clients. The delivery agents must deliver packages to the clients according to scheduling policies: rate-monotonic (exact), earliest-deadline first, and mixed scheduling.

Two versions are given for each of the three kinds of systems. All the six examples were specified in our input language which was then automatically translated by our translator into the HyTech input language. The results, as tabulated in Table 1, show that our approach indeed reduces the total size of the system state space for verification as compared to the pure model checking approach. Here, pure model checking means that we do not take advantage of the scheduling algorithms and directly verify the systems which might contain a lot of unschedulable states. Drastic reductions can be achieved in systems that have a heavy workload. With each type of example, either VOD or RTOS, it is observed that with a high complexity in the client automata (i.e., the number of modes and transitions) the SCBT implementation shows a larger benefit (i.e., a smaller state space size) compared to all the semantics of the SCAT implementation. This is due to the stronger semantics of a transition not occurring before the tasks schedulability of its destination mode is checked. Comparing the two semantics of SCAT: SSS and LSS, in all the examples it is observed that strict semantics shows a larger benefit with our approach. This is due to the stronger restriction in SSS of tasks required to be scheduled before the client can progress on. Thus, we can conclude that both theoretically and experimentally we have shown that SCBT has the strongest notion of schedulability and LSS of SCAT has the weakest notion with SSS of SCAT in-between SCBT and LSS.

5 Conclusion

Model-checking, though a popular verification method, has yet to be made more efficient for verifying the current highly complex systems. We have shown how complex

real-time systems can be easily verified using the popular model-checking approach if we model the complex system as a client-server scheduling system and then verify it. This approach is meaningful when we observe that almost all complex systems need some sort of scheduling so that the tasks can be executed consistently and efficiently. Our preliminary effort has been shown feasible through the implementation using our translator and the HyTech verification tool. Different semantics have been implemented and compared using several examples. Our future work will include the development of a tool devoted to the verification of such systems using symbolic model checking.
